

in permafrost-free areas near ridgetops. The unsaturated zone may consist of primarily organic soils in the active layer. The hydrologic role of these organic soils should not be underrated because they act as an important buffer, both hydraulically and thermally, between the atmosphere and mineral soil (Slaughter and Kane 1979). Soil moisture levels can vary, but generally high moisture levels exist in the active layer above permafrost. Better-drained soils with lower water contents are found in permafrost-free areas (Kane et al. 1978a). The permafrost is responsible for impeding drainage and for the development of high moisture levels. In turn, the high moisture levels dictate the type and density of vegetation and subsequent evapotranspiration rates.

The climatic variables of interest in groundwater recharge are the intensity, duration, and timing of the precipitation event. Low-intensity events allow infiltration to occur without producing runoff. High-intensity events may exceed infiltration rates and produce runoff. Duration of the event is important because longer events have greater potential for groundwater recharge. Timing of a hydrologic event is important because the source of water can be either snowmelt or rainfall, or a combination of both. In Alaska, except at high altitudes and along the coast, areas of continuous and discontinuous permafrost are classified as arid climates, based on annual precipitation. Both rainfall and snowmelt intensities are rather low. But the duration can be quite long, especially for snowmelt events. Whereas the occurrence of rainfall events are much less predictable, it is certain that a snowmelt event will occur every spring and that a potential for groundwater recharge exists because the snowpack can represent 40-80% of annual precipitation.

FIELD EVIDENCE OF GROUNDWATER RECHARGE

Reported here are selected results from numerous studies performed by the authors that help provide knowledge of the process of groundwater recharge in cold regions. Some comparative data on hydraulic properties of frozen soils that were reported by other authors are included in the latter part of this section.

Field data were collected near Fairbanks, Alaska, in an area of discontinuous permafrost. Permafrost is found on north-facing slopes and in valley bottoms; south-facing slopes are generally permafrost-free. The predominant soil type in this forested area is wind-deposited silt loam overlain with organic material. The thicknesses of the organic soils vary (generally 0-30 cm, thicker in permafrost areas) as do the mineral soils (0-60 m, greatest thickness in valley bottoms). Permafrost thicknesses can exceed 60 m. We collected field data with two primary goals (1) to assess the potential for groundwater recharge from rainfall and snowmelt events, and (2) to evaluate the potential for groundwater recharge in permafrost and nonpermafrost areas.

Recharge from Rainfall

Numerous studies (Kane, Seifert, and Taylor 1978, Kane et al. 1978b) have been carried out in which tensiometers installed at various depths were used to monitor soil moisture conditions. With a characteristic curve (pore pressure-moisture content relationship), one can estimate the moisture content from tensiometer readings, as well as determine the hydraulic gradient. From this, the direction of flow is determined. Tensiometer readings indicated that for nonpermafrost sites, the soils were very dry for much of the summer. Even during rainfall periods, very little reduction in the soil tensions occurred. The general trend was for the soils to become drier over the summer season. In unsaturated soils, lower moisture content yields lower hydraulic conductivity. For significant groundwater recharge to occur, strong downward vertical gradients are required. These did not occur. We concluded that most of the soil water was lost to evapotranspiration. Bralley (1980) examined evapotranspiration losses from barley and rapeseed near Delta, Alaska. We concluded that summer precipitation was equivalent to measured evapotranspiration.

Precipitation events have already been described as being of low intensity and of variable duration, resulting in low quantities of annual precipitation. From the tensiometer data (Luthin and Guyson 1974, Kane et al. 1978a), we concluded that little, if any, recharge occurs during the summer months. The only exception would be periods of sustained precipitation (> 3 cm), which are rare. We then looked at snowmelt as a source of groundwater recharge.

Snowmelt Lysimeters

The first attempt to quantify snowmelt infiltration into seasonal frozen soils was to construct several lysimeters that only allowed vertical movement of meltwater. These one-dimensional lysimeters are described by Kane et al. (1978a). Numerous lysimeters were built so that evaporation losses, moisture retention of organic soil, and moisture retention of mineral soil could be determined.

Some lysimeters collected and measured just snow. The next series of lysimeters collected snowfall, but the snowmelt had to flow through a 10-cm layer of organic material. The last series of lysimeters collected snowfall, and the snowmelt water flowed through the organic layer, plus a 20-cm layer of mineral soil. The system, associated processes, and type of results are shown in Figure 1. Water leaving the bottom of the lysimeters at base of snowpack, organic layer, and mineral layer was collected and measured. The data shown in the figure are for 1976, and the maximum water content prior to ablation of the snowpack was 10 cm. We measured between 17 April and 27 April that 2.1 cm of water was retained in the organic layer, 2.7 cm was retained in mineral soil, and 1.5 cm of water passed through the lysimeters. From this
